STATS 205: Final Project Write-Up

Brian Liu

6/14/2019

1. Background of the data and why it is interesting or important

The data we are using is the data from WHO suicide statistics from Kaggle. This gives population-based statistics on suicide rate.

The reason this data is interesting and important is that suicide is prevalent in many times and places around the world, but many places and times have different suicide rates. When it comes to suicide, there are many potential factors or attributes that may be correlated with an increased risk of suicide, such as:

- a person's sex
- the age group a person belongs to
- the generation a person was born in

The goal is to find significant correlations between these factors and suicide rates: that is, does x factor positively predict suicide rate?

The simple inspiration is suicide prevention: If we can identify the factors that correlate positively with, or predict high suicide rates, then we can target our suicide prevention efforts towards populations with those high-risk factors or attributes.

2. Explanation of the method studied and its properties

We will use the statistical techniques of nonparametric bootstrap and parametric bootstrap methods to aid in prediction, with linear regression as well, and use cross-validation to test if, given new data for a population, this population is at risk of suicide. In other words, predict if the suicide rate would be abnormally or significantly high, and then compare the performance between the two methods (nonparametric and parametric).

Bootstrapping

In statistics, bootstrapping is any test or metric that relies on random sampling with replacement. Bootstrapping allows assigning measures of accuracy (defined in terms of bias, variance, confidence intervals, prediction error or some other such measure) to sample estimates. This technique allows estimation of the sampling distribution of almost any statistic using random sampling methods. Generally, it falls in the broader class of resampling methods.

Bootstrapping is the practice of estimating properties of an estimator (such as its variance) by measuring those properties when sampling from an approximating distribution. One standard choice for an approximating distribution is the empirical distribution function of the observed data. In the case where a set of observations can be assumed to be from an independent and identically distributed population, this can be implemented by constructing a number of resamples with replacement, of the observed dataset (and of equal size to the observed dataset).

It may also be used for constructing hypothesis tests. It is often used as an alternative to statistical inference based on the assumption of a parametric model when that assumption is in doubt, or where parametric inference is impossible or requires complicated formulas for the calculation of standard errors.

Nonparametric vs. Parametric bootstrap

Linear regression - Kendall rank correlation coefficient

> In statistics, the Kendall rank correlation coefficient, commonly referred to as Kendall's tau coefficient (after the Greek letter τ), is a statistic used to measure the ordinal association between two measured quantities. A tau test is a non-parametric hypothesis test for statistical dependence based on the tau coefficient.

> It is a measure of rank correlation: the similarity of the orderings of the data when ranked by each of the quantities. It is named after Maurice Kendall, who developed it in 1938,[1] though Gustav Fechner had proposed a similar measure in the context of time series in 1897.[2]

> Intuitively, the Kendall correlation between two variables will be high when observations have a similar (or identical for a correlation of 1) rank (i.e. relative position label of the observations within the variable: 1st, 2nd, 3rd, etc.) between the two variables, and low when observations have a dissimilar (or fully different for a correlation of -1) rank between the two variables.

> Both Kendall's τ and Spearman's ρ can be formulated as special cases of a more general correlation coefficient.

Cross validation

3. Data analysis or simulation study

We will use the crude rate of suicide per 100,000 people.

> This analysis provides information on age-standardized rates...

```
who_suicide_statistics_df <- read.csv("who_suicide_statistics.csv")
head(who_suicide_statistics_df)
```

> After filtering countries with missing suicide rate, take a random sample of 100 countries and make sure each continent has approximately equal countries.

Filter countries by continent:

```
library(countrycode)
filtered_suicide_df$continent <- countrycode(sourcevar = filtered_suicide_df[, "country"],
                         origin = "country.name",
                         destination = "continent")
```

```
## Warning in countrycode(sourcevar = filtered_suicide_df[, "country"], origin = "country.name", : Some
```

```
## Warning in countrycode(sourcevar = filtered_suicide_df[, "country"], origin = "country.name", : Some
```

```
head(filtered_suicide_df)
```

```
##     country year    sex         age suicides_no population continent
## 25  Albania 1987 female 15-24 years          14     289700    Europe
## 26  Albania 1987 female 25-34 years           4     257200    Europe
## 27  Albania 1987 female 35-54 years           6     278800    Europe
## 28  Albania 1987 female  5-14 years           0     311000    Europe
## 29  Albania 1987 female 55-74 years           0     144600    Europe
## 30  Albania 1987 female   75+ years           1      35600    Europe
```

```
write.csv(filtered_suicide_df, 'filtered_suicide.csv')
```

Let us find out which continents are counted:

```
# Get list of continents
list_of_continents <- unique(filtered_suicide_df$continent); list_of_continents
```

```
## [1] "Europe"   "Americas" "Asia"     "Oceania"  "Africa"   NA
```

Therefore,

$$\frac{100 \text{ countries}}{6 \text{ continents}} \approx 16 \text{ to } 17 \text{ countries per continent}$$

we should randomly sample 17 countries from each continent.

Notably, there are countries that are not on any of the listed continents. Let us see which ones those are:

```
not_in_a_continent = filtered_suicide_df[is.na(filtered_suicide_df$continent),]
write.csv(not_in_a_continent, 'not_in_a_continent.csv')
head(not_in_a_continent)
```

```
##             country year     sex       age suicides_no population continent
## 32317 Rodrigues 2001 female 15-24 years           0         NA      <NA>
## 32318 Rodrigues 2001 female 25-34 years           0         NA      <NA>
## 32319 Rodrigues 2001 female 35-54 years           0         NA      <NA>
## 32320 Rodrigues 2001 female  5-14 years           0         NA      <NA>
## 32321 Rodrigues 2001 female 55-74 years           0         NA      <NA>
## 32322 Rodrigues 2001 female   75+ years           0         NA      <NA>
```

```
unique(not_in_a_continent$country)
```

```
## [1] Rodrigues           Virgin Islands (USA)
## 141 Levels: Albania Anguilla Antigua and Barbuda Argentina ... Zimbabwe
```

Let us make the choice not to include these countries in the analysis, since there are only two countries.

```
# Take off `NA` from list of continents
list_of_continents <- list_of_continents[-length(list_of_continents)]
list_of_continents
```

```
## [1] "Europe"   "Americas" "Asia"     "Oceania"  "Africa"
```

We will now create six dataframes, filtered by list of countries for each continent.

```
# library(rlist)
countries_per_continent <- list()

for (i in seq_along(list_of_continents))
{
    countries_per_continent[[i]] <- filtered_suicide_df[filtered_suicide_df$continent == list_of_contine
}

length(countries_per_continent)
```

```
## [1] 5
```

```
length(countries_per_continent)
```

```
## [1] 5
```

```
for (i in seq_along(countries_per_continent))
{
    print(head(countries_per_continent[[i]]))
    print(length(countries_per_continent[[i]]))
    cat("\n")
}
```

```
##    country year     sex       age suicides_no population continent
## 25 Albania 1987 female 15-24 years          14     289700    Europe
## 26 Albania 1987 female 25-34 years           4     257200    Europe
## 27 Albania 1987 female 35-54 years           6     278800    Europe

This text links to very important information about why a `for` loop doesn't print anything.[1]

Link to Pandoc Markdown formatting

Randomly sample 17 countries from each continent:

```
list_of_continents
```

```
## [1] "Europe"   "Americas" "Asia"     "Oceania"  "Africa"
```

```r
for (i in seq_along(countries_per_continent))
{
    print(list_of_continents[i])
    countries <- unique(countries_per_continent[[i]]$country)
    print(countries)
    print(length(countries))
    cat("\n")
```

---

[1] Basically, `for` loops are functions themselves. R prints out the result of a command automatically, but functions are not inherently a command, and since `for` loops are functions, nothing will be printed. The solution is to have `print(command())` within the `for` loop to get output for your `for` loop. You will never again spend hours trying to find out why a `for` loop doesn't print anything because you're no longer an R newbie.

```
}
```

```

```

Since there are only 5 countries in Oceania and 12 countries in Africa, we will use all 5 countries of Oceania and all 12 countries of Africa.

```
samples_of_countries <- list()
num_samples <- 17
for (i in seq_along(countries_per_continent))
{
    countries <- unique(countries_per_continent[[i]]$country)
    current_sample <- list()
    if (length(countries) >= num_samples)
    {
        current_sample <- sample(countries, 17)
    } else {
        current_sample <- sample(countries, length(countries))
    }
    samples_of_countries[[i]] <- current_sample
}
```

Let's see the countries that we will be sampling:

```
total <- 0
for (i in seq_along(samples_of_countries))
{
    print(list_of_continents[i])
    print(samples_of_countries[[i]])
    print(length(samples_of_countries[[i]]))
```

```
    total <- total + length(samples_of_countries[[i]])
    cat("\n")
}
```

```
## [1] "Europe"

```

Let's filter the original dataframe only to include countries that we have sampled:

```
countries_to_test <- list()
a <- 0
for (i in seq_along(samples_of_countries))
{
    # find out a way to access each country name
    # print each country name
    for (j in seq_along(samples_of_countries[[i]]))
    {
        sample <- samples_of_countries[[i]]
        country_string <- toString(sample[[j]])
        countries_to_test[a] <- country_string
        a <- a + 1
    }
}

length(countries_to_test)
```

```
## [1] 67
```

```
countries_to_test
```

```
